Abstract: Background: Placenta accreta is a general term used to describe the clinical condition when part of the placenta, or the entire placenta, invades and is inseparable from the uterine wall. Its incidence is growing due to the rising rate of cesarean sections and advanced maternal age on delivery. It is becoming the foremost cause of obstetric hemorrhage leading to significant maternal and fetal morbidity and even mortality. Rarely placenta accreta may lead to spontaneous uterine rupture in the second or third trimester. Case report: A 28-year-old woman gravida 4, para 3, was admitted at the maternity ward of Mendefera regional referral hospital, at a gestational age of 27 weeks due to vaginal bleeding. She had history of 3 time's caesarian section. At admission her vital sign was stable and her complete blood count was normal, ultrasound showed anterior placentation with partial placenta previa. She was given Dexamethasone 6 gm. IM twice daily for 2 days to enhance lung maturity. At 36 weeks of gestation, she experienced massive vaginal bleeding. A decision was made to perform emergency cesarean section. The possibility of morbidly adherent placenta was considered. Intra-operatively, the placenta was found with engorged blood vessels under the rectus fascia with ruptured uterus and there was adhesion of rectus sheath with part of the uterus. A transverse uterine incision was made at the upper border of the placental attachment to uterus to deliver the fetus. After successful delivery of the fetus, the placenta was found to be densely adhered to the lower uterine segment, penetrating through it and adhered to the posterior wall of the urinary bladder. It was decided to do caesarian hysterectomy with the placenta left in situ. During discharge both the mother and the baby were in good condition. Conclusion: Placenta accreta is a potentially life-threatening obstetric condition that requires a meticulous approach to management. If a multiparous woman with a previous caesarian section is found to have placenta previa, the possibility of placenta accreta should be considered in the diagnosis of the patient. Grayscale ultrasonography is sufficient for the diagnosis of placenta accreta. The recommended management of placenta accreta is planned caesarian hysterectomy.

Keywords: Placenta Previa, Caesarian Hysterectomy, Placenta Percreta, Outcome

1. Introduction

Placenta previa is the presence of placental tissue overlying or proximate to the internal cervical os. Its main complication is bleeding, which ranges from spotting to hemorrhagic [1, 2].

It is associated with severe maternal and fetal morbidity [3]. Its incidence is growing due to the rising rate of cesarean sections and advanced maternal age at delivery. The increasing incidence of cesarean delivery rate also leads to a marked increase in placenta accrete [1, 3]. Placenta accreta is a

general term used to describe the clinical condition when part of the placenta, or the entire placenta, invades and is inseparable from the uterine wall [4]. Both placenta previa and placenta accreta have the same major risk factors, namely tissue insult and scarring. The usual causes are previous cesarean section, myomectomy, hysteroscopic surgery, suture of uterine perforation, infection and dilatation and curettage [5, 6, 7]. In the presence of placenta previa, the risk of having placenta accreta rises from 24% in women with one cesarean section to 67% for women who had a history of three or more previous cesarean sections [8, 9]. Placenta accreta is associated with major pregnancy complications, spontaneous uterine rupture including life-threatening maternal hemorrhage, large-volume of blood transfusion, and peripartum hysterectomy, causing a significant maternal and fetal morbidity and even mortality [3, 9-11].

There are limited data on its treatment and optimal management [12]. Majority of women with placenta accreta require hysterectomy. Although successful conservative management has been described, there are currently inadequate data to endorse this approach as routine management [3, 9, 13].

2. Case Report

A 28-year-old woman (gravida 4, para 3) was admitted in Mendefera Regional Referral Hospital, Maternity ward, at gestational age of 27 weeks due to vaginal bleeding. The bleeding was bright red and moderate in amount but sudden in onset. The mother had a history of 3 caesarian sections. On admission her vital signs, CBC (complete blood count) and hemoglobin (14gm/dL) were normal, and her blood group was O⁺. Ultrasound examination showed normal fetal anatomy and growth, and confirmed the diagnosis of partial anterior placenta previa. The patient was informed about the diagnosis and its worst complications including the risk of preterm deliveries. She was given Dexamethasone 6 gm. intramuscular twice daily for 2 days to enhance lung maturity. Three units of blood were prepared for emergency operation. She was followed conservatively in the hospital for two months. During the follow-up period she had vaginal bleeding twice with moderate in amount. Her follow up ultrasound showed placenta previa with a loss of echo translucency behind the placenta.

At 36 weeks of gestation, she experienced massive vaginal bleeding and the possibility of morbidly adherent placenta was considered. A decision was made to perform emergency cesarean section. The patient and her family was informed all the possible complication, possible caesarian hysterectomies and its associated morbidity.

Under spinal anesthesia, the abdomen was opened in layer via lower midline incision. The placenta was found with engorged blood vessels under the fascia and there was adhesion of rectus sheath with part of the uterus. The uterus was ruptured and its upper and lower border was attached to the placenta (Figure 1). A transverse uterine incision was made at the upper border of the placental attachment to uterus.

A healthy female neonate weighing 2.5 kg with an Apgar score of 9/10 at 1st and 5th minute was delivered. The placenta was found to be densely adhered to the lower uterine segment, penetrating through it and adhered to the posterior wall of the urinary bladder. An attempt was made to dissect the bladder from the placenta and lower uterine segment which ends up on injuring the bladder. The bladder was inspected for infiltration of the placenta and there was no visible infiltration on the posterior wall of the bladder. During the manipulation, there was profuse bleeding. It was decided to do caesarian hysterectomy with the placenta left in situ. The bladder was repaired in two layers after the hysterectomy. Blood loss was estimated around 1.5 liters and the patient was transfused 2 units of blood and 3 liters of crystalloid after the end of the operation. Parenteral antibiotic was continued for 24 hrs.

The post-operative course was uneventful. The urinary catheter was left in place for 10 days. The patient was discharged on the 11th day of surgery voiding well. During her stays in the hospital there was no any complication, including urological problems. The neonate was active and feeding well during the hospital stay. The mother and the baby were discharged without any sequel.

3. Discussion

The incidence of placenta accrete has been reported to range 1 in 2,510 pregnancies in the 1980s and 1990s as compared to 1 in 533 pregnancies by the year 2002, and placenta percreta, the rarest form of placenta accreta, comprised from 5% to 7% of all placenta accrete [9, 14]. This rise in incidence rate is linked with persistent rise in caesarian section, uterine surgery, and increased parturient age and parity [1-4, 7, 15]. This condition has been present worldwide as the primary indication for emergency gravid hysterectomy which accounts for up to 50% of all emergency peri-partum hysterectomies [13]. In placenta percreta, rare variant of abnormal placentation with an incidence of 0.03 per 1,000, placenta villi grow in to the myometrium, reaching or penetrating the uterine serosa, possibly extending beyond to the intra-abdominal or pelvic organs [14]. Placenta accreta may lead rarely to spontaneous uterine rupture in the second or third trimester which is consistent to the case presented [9].

This 28-year woman was presented with most significant risk factors for placenta accreta (placenta percreta), namely 3 prior caesarian sections, anterior placenta previa and parity. If

a multiparous woman with a previous caesarian section is found to have placenta previa, the possibility of placenta accreta should be taken in to consideration during the diagnosis of the women, which is consistent to this case [9, 16, 17]. There are studies that described the incidence of placenta accreta as directly linked with the increase in cesarean delivery. A large multicenter cohort study reported that the risk of placenta accreta on those women with placenta previa and prior caesarean as 3%, 11%, 40%, 61%, and 67%; for first, second, third, fourth, and fifth or more cesarean deliveries, respectively, [14].

Recent population based studies also documented that placenta accreta remains undiagnosed before delivery in half to two thirds of the cases [14]. However, having the above information, one should suspect placenta accreta and look for signs of accreta and evaluation of villous myometrial invasion on ultrasound examination in a mother who had history of caesarian section and mid-trimester placenta previa on ultrasound examination. Results from prospective cohort study conducted by Finberg et al., and Comstock et al., indicated that the sensitivity of gray-scale imaging alone in diagnosing placenta previa accreta in women with a prior caesarean delivery is 93% and 86%, respectively [18, 19]. In this case ultrasound examinations revealed anterior placenta previa with loss of echo translucencies that leadsto be conscious of placenta accrete and decision was made to perform emergency cesarean section. The maternal morbidity in women with placenta accreta is high, especially in cases of placenta percreta. There are studies that indicated mortality due to placenta accreta ranges from 7% to 22% [3, 8]. Hemorrhage and disseminated intravascular coagulation being the main cause of maternal death. In this cases intra-operative blood losses of the mother was estimated to be around 1.5 liters for this she was transfused 2 units of whole blood. Even though this amount of blood loss was very minimal as compared to some studies that documented, a mean blood lose in such a case during peri-partum hysterectomy as 2.5 liter [3]. As many as 90% of patients with placenta accreta require blood transfusion, and 40% require more than 10 units of packed red blood cells [4]. Bladder injury is one of the intra-operative complications that might happen during operation as it presented in this case.

Generally, the recommended management of suspected placenta accreta is planned preterm cesarean hysterectomy with the placenta left in situ because removal of the placenta is associated with significant hemorrhagic morbidity [4, 12, 20, 21]. However the treatment options vary from conservative approach to caesarian hysterectomy. There are studies that reported the overweighing advantage of conservative treatment for placenta accrete in helping the women and reducing morbidity by avoiding hysterectomy [22]. But in such a case for a delivering woman, who had a previous history of uterine rupture, three previous caesarian, parity and patient's obstetric history; the decision was emergency cesarean hysterectomy as a lifesaving procedure without considering conservative management.

4. Conclusion

In conclusion, placenta accreta is a potentially life-threatening obstetric condition that requires a meticulous approach to management. Multiparous women with a history of myometrial damage caused by caesarian delivery with anterior placenta previa overlying the uterine scar are at risk of placenta accreta. Recognizing these obstetrics risk factors allow the identification of most cases during the antepartum period. Diagnosing placenta accreta before delivery allows appropriate planning in attempt to improve the outcome of this increasingly more common major obstetrical complication. Gray-scale Ultrasonography is sensitive and specific enough for its definitive diagnosis. In general, all precaution and preparation should be done for emergency management of such cases, and planned caesarean hysterectomy with the placenta left in situ is the recommended management of placenta accreta because attempts at removal of the placenta are associated with significant hemorrhagic morbidity.
